# Carbon-dot Sensitized and N-doped TiO<sub>2</sub> in Mesoporous Silica for Water Decontamination through Non-hydrophobic Enrichment-Degradation Mode

Chen Cheng<sup>1</sup>, Lingzhi Wang<sup>1,2\*</sup>, Tapas Sen,<sup>3</sup> Juying Lei,<sup>1</sup> Ahmed Mohamed El-Toni<sup>4,5</sup>, Jinlong Zhang,<sup>1\*</sup> Fan Zhang<sup>2\*</sup> and Dongyuan Zhao<sup>2</sup>

**Abstract:** Mesoporous silica synthesized from the co-condensation of tetraethoxysilane and silylated carbon dot containing amide group has been adopted as the carrier for the in-situ growth of TiO<sub>2</sub> through an impregnation-hydrothermal crystallization process. Benefitted from the initial complexing between the titania precursor and carbon dot, highly dispersed anatase TiO<sub>2</sub> nanoparticles can be formed inside the mesoporous channel. The hybrid material possesses ordered hexagonal mesostructure with a *p6mm* symmetry, high specific surface area (446.27 m<sup>2</sup>g<sup>-1</sup>), large pore volume (0.57 cm<sup>3</sup>g<sup>-1</sup>), uniform pore size (5.11 nm) and a wide absorption band between 300–550 nm. TiO<sub>2</sub> nanocrystals are anchored to carbon dot through bonds of Ti–O–N and Ti–O–C as revealed by X-ray photoelectron spectroscopy. Moreover, the nitrogen doping of TiO<sub>2</sub> is also verified by the formation of Ti–N bond. This composite shows excellent adsorption capability to organic 2, 4-dichlorophenol and acid orange 7 with electron-deficient aromatic ring through the electron donor-acceptor interaction between carbon dot and organics instead of hydrophobic effect as analyzed by the contact angle analysis, which can be photocatalytically recycled through visible light irradiation after the adsorption. The narrowed bandgap by nitrogen doping and the photosensitization effect of carbon dot are revealed to be co-responsible for the visible-light activity of TiO<sub>2</sub>. The adsorption capacity does not suffer obvious loss after being recycled 3 times.

## Introduction

TiO<sub>2</sub> semiconductor with good chemical stability has drawn most attention as photocatalysts for new energy development and pollutant degradation<sup>[1]</sup>. Nanometer-sized TiO<sub>2</sub> has superior photocatalytic activity to bulk counterpart since it has more surface-active sites and higher electron-hole separation rate<sup>[2]</sup>. Many efforts have been devoted to decrease the particle size. However, the side effects of size-reduction lie in that nanometer-

sized TiO<sub>2</sub> have strong agglomeration tendency and narrowed light-absorption range due to the quantization-size effect.<sup>[3]</sup> To solve the above ubiquitous contradictions encountered during the photocatalysis application, intensive studies about loading photocatalyst on carrier with large specific surface area, and doping or sensitization of TiO<sub>2</sub> to extend the light absorption range of TiO<sub>2</sub><sup>[4]</sup> have been respectively or jointly carried out.

Mesoporous silica with a large specific surface area, modifiable framework surface and tunable pore size from 2–50 nm has proven to be good carriers for the loading of photocatalysts by versatile methods including co-assembly, in-situ growth and post-impregnation<sup>[5]</sup>. Additional treatment has also been utilized to activate loaded TiO<sub>2</sub> in visible light range. For examples, Ti–O–Cr<sup>[6]</sup>, Ti–O–Ce<sup>[7]</sup> have been formed in mesoporous silica to improve the visible light activity. Moreover, in consideration of the abundant porous system, mesoporous silica can simultaneously play the role of pollutant adsorption<sup>[8]</sup>, improving the photocatalytic activity through the pollutant-enrichment effect. To achieve the cooperative effect between adsorption and photocatalysis, the reasonable spatial arrangement and uniform dispersion of adsorption and photocatalysis sites are essential, which however has not got efficiently solved due to the great reactivity of most titania precursors with low electronegativity and the high coordination numbers<sup>[9]</sup>. Uncontrollable growth and local aggregation have been commonly observed, which discount the cooperative effect of adsorption and photocatalysis.

Here, we adopt a silylated carbon dot (CD)<sup>[10]</sup> composed of graphitic core and amide-covered surface for the formation of mesoporous silica through the co-condensation of CD and tetraethoxysilane (TEOS). Through the complexing of amide groups with Ti(SO<sub>4</sub>)<sub>2</sub> precursor and a hydrothermal crystallization process, highly dispersed TiO<sub>2</sub> are subsequently in-situ grown in the pore channels without sacrificing the pore accessibility. TiO<sub>2</sub> nanoparticles are nitrogen-doped and bridged to CD through Ti–O–C and Ti–O–N bonds. This composite shows high adsorption efficiency to 2, 4-dichlorophenol (2, 4-DCP) and azo dye acid orange 7 (AO7) through electron donor-acceptor interaction between CD and organics. The enriched organics around TiO<sub>2</sub> can be photocatalytically degraded under visible light irradiation. The visible-light activity is attributed to the co-effect of nitrogen-doping and CD sensitization. The adsorption-degradation process can be recycled 3 times without causing obvious loss of adsorption capacity.

## Results and Discussion

CD is formed from the pyrolysis reaction of citric acid in amine-containing silane<sup>[10]</sup>. The product sealed in hexane is sticky and yellowish brown and the film spin-coated from the hydrolyzed CD shows yellow color (Fig. 1A). The UV-Vis diffuse reflectance spectrum of CD film shows a wide absorption band

from 300 to 550 nm. (Fig. 1 B). The Fourier transform infrared (FTIR) spectrum shows bands at 1520–1650, 960–1140 and 698–860  $\text{cm}^{-1}$  ascribed to the vibrations of  $\text{CONH}_2$ , Si–O and Si–CH<sub>2</sub> groups, respectively (Fig. 1 C). The high-resolution transmission electron microscopy (HRTEM) shows that CD is monodispersed and polycrystallized with particle size of 1–2 nm (Fig. 1 D).

**Figure 1.** Optical photographs of the hexane solution of CD (left) and the film obtained by spin-coating the hydrolysed CD on glass slide (right); (B)-(D) UV-Vis diffuse reflectance and FTIR spectra and HRTEM image of CD nanoparticles. Insert: Histogram of the particle diameter distribution (Left) and the enlarged HRTEM image (Right) of CD.

CD-embedded mesoporous silica (CD-MS) was synthesized according to our previous report, which uses CD and TEOS as the co-precursor of silica and  $\text{EO}_{20}\text{PO}_{70}\text{EO}_{20}$  (P123) as the template<sup>[10d]</sup>.  $\text{TiO}_2$  nanoparticles were subsequently in-situ formed on CD-MS using  $\text{Ti}(\text{SO}_4)_2$  as the titania precursor through the process of impregnation and hydrothermal crystallization (Ti-CD-MS). TEM images indicate that highly dispersed  $\text{TiO}_2$  nanocrystals (ca. 4 nm) can be formed in the pore channel of CD-MS (Fig. 2 A), while severely local aggregation occurs for  $\text{TiO}_2$  particles grown on MS (Ti-MS, Fig. 2 B), indicating the formation of uniformly distributed  $\text{TiO}_2$  nanocrystals on CD-MS should be related to the existence of CD in the pore channel. It is known that chelating agent with mercapto, amine or carbonyl group is advantageous to inhibit the growth of metal or metal oxide nanoparticles through forming metal ion complex<sup>[11]</sup>. Therefore, the amide group of CD should be responsible for suppressing the severe hydrolysis of titania precursor and the subsequent agglomeration of  $\text{TiO}_2$ . The wide-angle X-ray powder diffraction (XRD) pattern shows that  $\text{TiO}_2$  nanocrystal has anatase phase and the low intensity is ascribed to the tiny size of anatase  $\text{TiO}_2$  (Fig. 2 C). The small-angle XRD pattern shows a peak at  $2\theta = 0.834^\circ$  ascribed to 10 reflection of a 2D hexagonal mesostructure with a space group of  $p6mm$ <sup>[5b]</sup>, indicating that the mesostructure is still retained after the introduction of  $\text{TiO}_2$  (Fig. 2 D). The  $\text{N}_2$  adsorption-desorption isotherms (Fig. 2 E) indicates this hybrid material has typical type IV curves with sharp capillary condensation steps in the middle  $P/P_0$  range. The specific surface area is calculated to be

$\sim 446.27 \text{ m}^2\text{g}^{-1}$  by Brunauer–Emmett–Teller (BET) method. A narrow pore-size distribution curve with the mean value of  $\sim 5.11 \text{ nm}$  is obtained from the adsorption branch using Barrett–Joyner–Halenda (BJH) model (Fig. 2 F). The pore volume is about  $0.57 \text{ cm}^3/\text{g}$ . These data are comparable to those of CD-MS without embedding of  $\text{TiO}_2$  (Fig. S1), indicating the pore system is not blocked due to the introduction of  $\text{TiO}_2$  into the pore channel.

**Figure 2.** TEM images of Ti-CD-MS (A) and Ti-MS (B); Wide-angle XRD pattern (C), small-angle XRD pattern (D),  $\text{N}_2$  adsorption-desorption isotherms (E) and pore size distribution curve (F) of Ti-CD-MS.

The element mapping by energy dispersive X-ray (EDX) spectroscopy shows that element Ti is uniformly distributed on mesoporous silica accompanied with element N, which is derived from the amide groups on CD (Fig. 3). The weight percentage contents of Si, Ti and N are 37.9, 19.0 and 5.2 wt%, respectively. Fig. 4 a shows the X-ray photoelectron spectroscopy (XPS) for the Ti 2p region of Ti-CD-MS and Ti-MS. The  $\text{Ti}2p_{3/2}$  and  $\text{Ti}2p_{1/2}$  core levels of Ti-MS appearing at 467.2 and 461.2 eV are higher than most of the reported values<sup>[12]</sup>, which should be related to the loading environment of  $\text{TiO}_2$  nanoparticle and will be discussed together with the O1s spectrum later. The two peaks shift to 465 and 459 eV for sample Ti-CD-MS, indicative of the increased electron density caused by the presence of CD<sup>[12a]</sup>. The N1s spectrum shows a broad peak centered at 401.6 eV, which is accompanied by a small peak at 396.8 eV. It is commonly accepted that the peak around 396 eV is ascribed to the substitutional nitrogen (Ti–N) and the peak at 401.6 eV is assigned to the oxidized Ti–N in the

form of Ti-O-N<sup>[12a, 13]</sup>. The C1s XPS peak can be fitted into three peaks at 284.6, 285.5 and 288.4 eV. The first peak at 284.6 eV

Figure 3. EDX mapping of elements Si, Ti and N in Ti-CD-MS. The scale bar is 100 nm.

is associated with the adventitious elemental carbon. The second peak at 285.5 eV is assigned to graphitic carbon and the small peak at 288.4 eV proves the existence of C=O and COO<sup>[14]</sup>. Therefore, it is assumed that CD obtained from instant high-temperature pyrolysis of citric acid in the presence of amine-containing silane should be composed of a graphitic carbon core covered with an ethoxysilane shell through the linkage of amide group according to the result from UV-Vis, FTIR and C1s XPS. Moreover, the peak at 281.2 eV corresponding to the Ti-C bond was not observed<sup>[14]</sup>, suggesting C atoms in CD may be bonded with lattice oxygen atoms in TiO<sub>2</sub> as Ti-O-C through substituting titanium atoms instead of replacing oxygen atoms. The fitting of O1s spectrum generates three peaks at 529.6 eV, 532.0 eV and 535.2 eV. The peak at 529.6 eV is from Ti-O-Ti and the peak at 532 eV is ubiquitously observed from TiO<sub>2</sub> with Ti-O-C or Ti-O-N<sup>[12a, 15]</sup>. The content of these two species cannot be discriminated according to the similar electronegativity of C and N. The highest peak at 535.2 eV is related to the existence of abundant O-H bonds in mesoporous silica, which may lead to the electron deficiency of Ti species loaded in the pore channel and is accordant with the Ti 2p XPS of Ti-MS. Based on the formation of Ti-O-N, Ti-O-C and Ti-N bonds, it is proposed that Ti precursor should be chelated by O=CNH<sub>2</sub> groups in CD, which prohibits the growth of TiO<sub>2</sub> particle during the hydrothermal process. The finally formed TiO<sub>2</sub> particles should be attached on CD particles through Ti-O-N and Ti-O-C bonds and part of N is doped into the lattice of TiO<sub>2</sub> in the form of Ti-N.

The UV-Vis absorption spectrum of Ti-CD-MS shows a wide absorption band from 300 to 550 nm (Fig. 5 A). When irradiated

with the visible light, Ti-CD-MS shows photocurrent much higher than CD-MS (75 times) in the absence of TiO<sub>2</sub> and Ti-MS (30 times) in the absence of CD (Fig. 5 B). The visible-light activity can be attributed to N doping. However, in consideration of the

Figure 4. XPS spectra of Ti-MS and Ti-CD-MS: Ti2p (A), C1s (B), O1s (C) and N1s (D).

graphitic essence of CD, the highest occupied molecular orbital (HOMO) and lowest unoccupied molecular orbital (LUMO) levels of CD has been further calculated to reveal the possibility of photosensitization of TiO<sub>2</sub> by neighboring CD bridged through Ti-O-N and Ti-O-C<sup>[16]</sup>. First, the energy bandgap ( $E_g$ ) of CD-MS is determined to be ca. 2.51 eV (Fig. 5 C) from the Tauc plot of transformed Kubelka-Munk function versus  $h\nu$  as indicated in Equation 1<sup>[17]</sup>:

$$(\alpha h\nu)^{1/2} \text{ vs. } (h\nu - E_g) \dots\dots\dots (1)$$

$$HOMO = -[E_{ox} - E_{Fc/Fc^+} + 4.5 + 0.24] \text{ eV} \dots\dots\dots (2)$$

$$LUMO = HOMO + E_g \dots\dots\dots (3)$$

Where  $\alpha$  is the absorption coefficient,  $\nu$  is the frequency of the light, and  $h$  is Planck's constant. The onset potential of oxidation ( $E_{ox}$ ) of CD-MS is measured as 0.11 V by cyclic voltammetry using saturated calomel electrode (SCE) as the reference electrode and ferrocene as the standard (Fig. 5 D). The potential of SCE is 0.24 V versus standard hydrogen electrode (SHE). The oxidation potential of ferrocene ( $E_{Fc/Fc^+}$ ) is 0.42 V versus SHE (inset, Fig. 5 D). According to the absolute potential of SHE (-4.5 eV), the HOMO level of CD-MS is calculated to be -4.49 eV from the oxidation potential using Equation 2. **The LUMO level of CD-MS is calculated to be -1.98 eV from Equation 3., allowing the electron transfer from CD-MS to anatase TiO<sub>2</sub> with lower**

potential of conduction band ( $-4.42$  eV) when irradiated with visible light and resulting in the photosensitization of  $\text{TiO}_2$  by neighboring CD<sup>[18]</sup>. Therefore, the improved photocurrent of Ti-CD-MS under visible light irradiation should be attributed to the co-effect of nitrogen-doping and CD-sensitization of  $\text{TiO}_2$ .

**Figure 5.** (A) UV-Vis spectra of Ti-CD-MS, CD-MS and MS; (B) Photocurrent of Ti-CD-MS, CD-MS and Ti-MS under visible-light irradiation; (C) Optical energy band gap and CV curve of CD-MS.

**Figure 6.** Adsorption-photocatalytic recycling efficiency of Ti-CD-MS for 2, 4-DCP (A) and AO7 (B).

Furthermore, it is found Ti-CD-MS shows significant adsorption capacity to 2, 4-DCP in the dark when applied as a photocatalyst, where about 75 % of 2, 4-DCP can be adsorbed after the equilibrium was reached within 1.0 h as verified by UV-Vis absorption spectra (Fig. 6 A). The high adsorption efficiency should be related to the incorporation of CD since Ti-MS shows less adsorption. The isoelectric point of Ti-CD-MS is at  $\text{pH}=4.8$  (Fig. S2), which excludes the possibility of electrostatic interaction between 2, 4-DCP and Ti-CD-MS at neutral environment. The hydrophobicity test was further carried out to identify the contribution of hydrophobic interaction due to the presence of graphitic carbon in CD. The contact angle of Ti-CD-MS is about  $55.23^\circ$  (Fig. S3), which seems incompetent to the pronounced adsorption capacity as demonstrated in Fig. 6A since the surface of Ti-CD-MS is actually hydrophilic. Currently, for the enrichment-assisted photocatalysis, hydrophobic

interaction is commonly adopted. In general, hydrophobic interaction refers to the adsorption behavior of aromatic compounds without polar functional groups through weak Van der Waals force. Besides hydrophobic interaction, other adsorption modes including polar- $\pi$  interactions, cation- $\pi$  and  $n-\pi$  electron donor-acceptor (EDA) interaction have been reported<sup>[9]</sup>. 2, 4-DCP contains an electron-deficient  $\pi$ -system due to the presence of two electron-withdrawing -Cl substituents on aromatic ring. Ti-CD-MS contains amide group, where the O and N atoms should also possibly form  $n-\pi$  EDA interaction with the electron-deficient  $\pi$ -system. The binding affinity of  $n-\pi$  EDA interaction is stronger than that caused by hydrophobic interaction since the bonding enthalpies involved in hydrophobic interactions are considered negligible compared with EDA interaction<sup>[10c]</sup>. The advantage of non-hydrophobic adsorption lies in the preservation of hydrophilicity of photocatalyst, which is more feasible for the treatment of sewage water. Since  $\text{TiO}_2$  nanocrystals are anchored with CD through Ti-O-N and Ti-O-C bonds, the enrichment of pollutant by CD can increase the local concentration of pollutant around  $\text{TiO}_2$ . The absorption of 2, 4-DCP keeps decreasing by further irradiated with visible light for 1 h. The degradation of adsorbed 2, 4-DCP was verified by analyzing the elution obtained from washing photocatalyst with ethanol after the photocatalysis process with UV-Vis spectroscopy. No absorption attributed to 2, 4-DCP is detected from the elution, indicating the efficient degradation of adsorbed 2, 4-DCP. The degradation of total 2, 4-DCP in solution can be achieved by prolonging the irradiation time (4 h, Fig. S5). However, the photocatalyst can actually well recover its adsorption capacity after 1 h of irradiation, which still preserves its 87 % of adsorption capacity at the 3rd recycle (Fig. 6A). The well preserved adsorption capacity demonstrates the good photostability of CD. In fact, CD shows negligible variation of peak intensity even after 4 h of irradiation with 300 W of Xe lamp (Fig. S4). Moreover, to demonstrate the effect of  $n-\pi$  EDA interaction on pollutant adsorption, azo dye AO7 also containing the electron-deficient aromatic ring was further adopted as pollutant target as shown in Fig. 6B. About 90% of AO7 is adsorbed after the equilibrium is reached within 0.5 h. The adsorbed AO7 is almost completely eliminated after further irradiated with visible light for 1 h. The recycled Ti-CD-MS can still adsorb 90% of AO7 and be further recycled for 3 times without obvious loss of adsorption capacity. As mentioned above, the excellent visible-light driven photocatalytic self-recycling performance should be benefitted from the co-contribution from nitrogen-doping and CD-sensitization of  $\text{TiO}_2$  (Fig. 7).

**Figure 7.** Schematic diagram for the visible-light driven photocatalytic self-recycling process.

## Conclusions

In conclusion, mesoporous silica embedded with amide-containing CD was used for the in-situ growth of  $\text{TiO}_2$  photocatalyst. Highly dispersed  $\text{TiO}_2$  nanocrystals are formed in the pore channel through the chelating between amide groups and titania precursor. Under the visible-light irradiation, Ti-CD-MS shows photocurrent 75 times higher than CD-MS and 30 times higher than Ti-MS due to the co-effect of nitrogen-doping and photosensitization of  $\text{TiO}_2$  by neighboring CD. When applied to the photocatalytic elimination of 2, 4-DCP and AO7, Ti-CD-MS shows extraordinary activity through the enrichment-degradation mode since CD can efficiently adsorb 2, 4-DCP and AO7 with electron-deficient aromatic ring via  $\pi$ - $\pi$  EDA interaction. In consideration of the high feasibility of the non-hydrophobic adsorption mode for the water decontamination, we believe the design and synthesis strategy presented here can further accelerate the development and application of enrichment-degradation type photocatalyst for the wastewater treatment.

## Experimental Section

### Synthesis of CD

CD was prepared through a one-step synthetic route reported previously.<sup>[10a]</sup> First, 10 mL of N-( $\beta$ -aminoethyl)- $\gamma$ -aminopropyl methyltrimethoxy silane (AEAPMS) was put in a 50 mL of three-necked flask. The temperature was increased to 240 °C under nitrogen atmosphere. Then 0.5 g of anhydrous citric acid was quickly added into the flask. The reactants were heated at 240 °C for 1 min and then cooled to room temperature. The sample was obtained after washed with hexane for two times, then sealed with hexane and stored in the refrigerator.

### Synthesis of CD encapsulated mesoporous silica (CD-MS)

CD-MS was prepared using  $\text{EO}_{20}\text{PO}_{70}\text{EO}_{20}$  (P123) as the template following the method described previously.<sup>[5b]</sup> P123 was first dissolved in 120 mL of HCl solution (2.0 M) to get a homogeneous solution by vigorous stirring at 38 °C. Then, 9 mL of TEOS and 0.6 mL of CD were added and the mixture was stirred at 38 °C for 24 h. After that, the mixture was transferred into an autoclave and hydrothermally treated for 24 h at 100 °C. Then the samples were filtered, washed with deionized water, and dried at 60 °C under vacuum condition. The templates were removed by solvent-extraction method, where 50 mg of the as-made sample, 60 mg of sodium acetate and 5 mL of ethanol were mixed together and stirred under refluxing at 92 °C for 1 h.

### Loading of $\text{TiO}_2$ nanoparticles on CD-MS (Ti-CD-MS)

$\text{TiO}_2$  nanoparticles were loaded on CD-MS through precursor-impregnation and *in-situ* hydrothermal growth. First, 25 mg of  $\text{Ti}(\text{SO}_4)_2$  was dissolved in a solution containing 22 mL of ethanol and 3 mL of deionized water. Then 0.1 g of CD-MS was added under stirring. After

further stirring at room temperature for 3 h, the mixture was transferred to an autoclave and hydrothermally treated at 120 °C for 12 h. The obtained product was washed by deionized water and dried at 60 °C for 12 h under the vacuum condition.  $\text{TiO}_2$  was also in-situ loaded on MS through the same procedure (Ti-MS).

### Photocatalytic experiments

50 mg of sample and 50 mL of 2, 4-dichlorophenol (2, 4-DCP, 10 mg/L) or azo dye acid orange 7 (AO7, 10 mg/L) were ultrasonically mixed. Before irradiation, the mixture was stirred for 30 min in the dark to reach an adsorption-desorption equilibrium. A 300 W high-pressure Xe lamp equipped with 420 nm optical filter was used as the light source. Ambient temperature was maintained during the photocatalytic reaction. At each predetermined time point, the analytical samples taken from the mixture were immediately centrifuged and then filtered through syringe filters (cellulose acetate membranes) with the size of 0.22  $\mu\text{m}$  to remove the photocatalysts. The filtrates were analyzed by recording variations in the UV-Vis absorption spectra of 2, 4-DCP or AO7.

### Characterization

X-ray diffraction (XRD) patterns were collected on a RigakuD/MAX 2550 diffractometer using Cu K $\alpha$  radiation (40 kV, 100 mA,  $\lambda = 0.15406$  nm).  $\text{N}_2$  sorption isotherms were measured at 77 K by a Micromeritics ASAP 2020 analyzer. The Brunauer–Emmett–Teller (BET) method was utilized to calculate the specific surface areas (SBET) by using the Barrett–Joyner–Halenda (BJH) model, the pore volumes and pore size distributions were derived from the adsorption branches of isotherms. The transmission electron microscopy (TEM) was conducted on a JEM 2000EX microscope. Fourier Transform Infrared (FT-IR) spectra were recorded from a Nicolet FTIR spectrometer (Nicolet Magna 550). UV-Vis absorption or diffuse reflection spectra were performed on a Scan UV-Vis spectrophotometer (SHIMADZU, UV-2450), with  $\text{BaSO}_4$  as the reflectance sample. Zeta-potential vs. pH curves were analyzed by a Malvern Zetasizer Nano-ZS instrument (ZEN3600, Malvern Instruments), using 0.1 M of NaOH and HCl to adjust the pH value, and 0.1 M of NaCl to maintain a high background-electrolyte concentration. For the electrochemical analysis, the counter, reference and working electrodes are Pt electrode, saturated calomel electrode (SCE) and FTO glass coated with thin film of tested sample, respectively. **The supporting electrolyte is a mixed solution of (2.5 mM)  $\text{K}_3\text{Fe}(\text{CN})_6$  and (0.1 M) KCl, where  $\text{K}_3\text{Fe}(\text{CN})_6$  is used as an internal standard.** The electrode potential is 0.24 V versus normal hydrogen electrode (NHE). The scan rate is 100 mV/s.
